V. RESULTS
VI. SUMMARY AND CONCLUSIONS
VII. REFERENCES

- Data from 5873 observational rainfall stations and 288 NCEP gridcells
- Restrict to 1970-1999 summer data and stations with no more than $10 \%$ missing data
- Threshold set at a given percentile of all available observations (including Os)
- No declustering - assume each day is independent of every other
- Fit "point process" form of POT model and calculate 50year return values
- For each grid cell containing at least 10 observational stations, compute RV50 from pooled data and compare with gridcell RV50
- Ratios of point to grid RV50 range from 1.34 to 8.85

OBSV 50-Year Return Values

NCEP 50-Year Return Values

Ratio OBSV:NCEP

Objectives of the study:

1. Use spatial statistics to interpolate daily data and thereby estimate a grid-cell average for each day
2. Estimate 50-year return values based on estimated daily gridcell averages
3. Provide an independent evaluation of how well NCEP is doing

The objectives are different from Elizabeth Shamseldin's project presented last week because I don't directly address the downscaling issue. I view it as a complementary project aimed at evaluating the quality of NCEP or any other reanalysis or RCM we may choose to examine.
II. STATISTICAL MODEL

- Fit GEV to tails of distribution - equivalent to

$$
1-F(y)=\operatorname{Pr}\{Y>y\} \approx \frac{1}{T}\left(1+\xi \frac{y-\mu}{\psi}\right)_{+}^{-1 / \xi}, y \geq u
$$

$u$ is threshold, $x_{+}=\max (x, 0)$ and $T$ is number of relevant days per year (here 92)

- Estimate $F(0)$ by sample proportion of zeros
- For $0<y<u$, divide range into 20 equiprobable intervals and assume $F(y)$ is piecewise linear within each interval. Thus we have an estimate of $F(y)$ for the entire range of $y$
- Define $Z=\Phi^{-1}(F(Y))$ so that $Z$ has marginal $N[0,1]$ distribution. Values $Y=0$ are transformed into $u^{*}=\Phi^{-1}(F(0))$ which becomes the natural threshold - $Z$ values censored at $u^{*}$.
- We assume the underlying $Z$ process is a Gaussian spatial process.

Related ideas in the literature:

Coles and Tawn (1996) developed a similar approach but assuming $Z$ is max-stable. They argued that this is more suitable for studying extremal properties but it is unclear how realistic this model is. Also, their paper is based on a particular representation of max-stable processes and the estimation methods are computationally intensive for the kind of applications we have in mind.

Sansó and Guenni $(2000,2004)$ proposed an embedded Gaussian model similar in spirit to what I propose here. They fitted the model in a fully Bayesian approach with MCMC. However their data examples are much more limited than the data considered here and I question whether a computationally intensive MCMC approach is feasible for this problem.

## III. ESTIMATING A THRESHOLDED GAUSSIAN PROCESS

Basic model: $Y=\left(Y_{1}, \ldots, Y_{n}\right)^{T}$ has a multivariate normal distribution, $N[0, \Sigma(\theta)]$ where $\Sigma(\theta)$ is a known function of finitedimensional parameter $\theta$. However we observe only those values $Y_{i}$ for which $Y_{i}>u$ - rest are censored.

This model is replicated independently for each of $N$ days.
How should we estimate $\theta$ ?
On any given day, let $A=\left\{i: Y_{i}>u\right\}$ and $B=\left\{i: Y_{i} \leq u\right\}$. Suppose $|B|=m$. Also let $Y_{A}, Y_{B}$ be the corresponding subvectors.

If we condition on $Y_{A}$, then we can write down the (MVN) conditional distribution of $Y_{B}$. Therefore, the contribution from this day to the exact likelihood is given by

$$
f\left(Y_{A}\right) \times \operatorname{Pr}\left\{Y_{i} \leq u, \quad i \in B \mid Y_{A}\right\}
$$

and could be evaluated exactly if we had an efficient algorithm to evaluate the $m$-dimensional multivariate normal distribution.

Option 1: Use exact or simulated MVN distribution function.

Exact algorithms due to, e.g. Schervish (1984), but does not work well in high dimensions. Usual recommendation in high dimensions is simulation, but this takes us back to MCMC evaluation.

Option 2: Use EVT approximation to MVN distribution.

Possible use of Stein-Chen method, e.g. Roos (1994), Raab (1998)

It's not clear to me that the error in such approximations is small (in this sort of context), or exactly how one would determine that issue.

Option 3: Break up into a series of bivariate normal approximations, for which there are well-established algorithms, e.g. Owen (1956), Donnelly (1973), Young and Minder (1974).

So if we reorder the data so that $B=\{1, \ldots, m\}, A=\{m+1, \ldots, n\}$, the idea is to approximate $\operatorname{Pr}\left\{Y_{i} \leq u, i=1, \ldots, m \mid Y_{A}\right\}$ by

$$
\begin{aligned}
\operatorname{Pr}\left\{Y_{1} \leq u \mid Y_{A}\right\} & \times \operatorname{Pr}\left\{Y_{2} \leq u \mid Y_{1} \leq u, Y_{A}\right\} \\
& \times \operatorname{Pr}\left\{Y_{3} \leq u \mid Y_{2} \leq u, Y_{A}\right\} \\
& \vdots \\
& \times \operatorname{Pr}\left\{Y_{m} \leq u \mid Y_{m-1} \leq u, Y_{A}\right\}
\end{aligned}
$$

Problem with this: does not lead to consistent estimators.

Consider $n=3$. Break up likelihood into 8 components corresponding to $\left(Y_{1}>u, Y_{2}>u, Y_{3}>u\right),\left(Y_{1}>u, Y_{2}>u, Y_{3} \leq u\right), \ldots$, ( $Y_{1} \leq u, Y_{2} \leq u, Y_{3} \leq u$ ). Only the last of these is different from exact MLE so let's concentrate on that case.

Exact likelihood would be

$$
\operatorname{Pr}\left\{Y_{1} \leq u\right\} \cdot \operatorname{Pr}\left\{Y_{2} \leq u \mid Y_{1} \leq u\right\} \cdot \operatorname{Pr}\left\{Y_{3} \leq u \mid Y_{1} \leq u, Y_{2} \leq u\right\}
$$

Approximate this by

$$
\operatorname{Pr}\left\{Y_{1} \leq u\right\} \cdot \operatorname{Pr}\left\{Y_{2} \leq u \mid Y_{1} \leq u\right\} \cdot \operatorname{Pr}\left\{Y_{3} \leq u \mid Y_{2} \leq u\right\}
$$

The difference in log likelihoods is

$$
\ell_{\text {approx }}-\ell_{\text {exact }}=\log \frac{\operatorname{Pr}\left\{Y_{3} \leq u \mid Y_{2} \leq u\right\}}{\operatorname{Pr}\left\{Y_{3} \leq u \mid Y_{1} \leq u, Y_{2} \leq u\right\}}
$$

When this is differentiated with respect to $\theta$ we have

$$
E\left\{\frac{\partial \ell_{\text {exact }}}{\partial \theta}\right\}=0
$$

and so

$$
\begin{aligned}
E\left\{\frac{\partial \ell_{\text {approx }}}{\partial \theta}\right\}= & \frac{\partial}{\partial \theta}\left\{\log \frac{\operatorname{Pr}\left\{Y_{3} \leq u \mid Y_{2} \leq u\right\}}{\operatorname{Pr}\left\{Y_{3} \leq u \mid Y_{1} \leq u, Y_{2} \leq u\right\}}\right\} \\
& \cdot \operatorname{Pr}\left\{Y_{1} \leq u, Y_{2} \leq u, Y_{3} \leq u\right\} .
\end{aligned}
$$

Unless $Y_{1}$ and $Y_{3}$ are conditionally independent given $Y_{2}$, this expression will not be 0 .

In other words, the estimating equations are not unbiased. Typically this is a necessary condition for consistency.

However, this suggests another approach.

Option 4: Apply the pairwise principle to the whole of the likelihood, not just part of it.

In other words, for a fixed ordering of indices, replace exact LH

$$
L\left(Y_{1}\right) \cdot L\left(Y_{2} \mid Y_{1}\right) \cdot L\left(Y_{3} \mid Y_{2}, Y_{1}\right) \ldots
$$

by a pairwise approximation

$$
L\left(Y_{1}\right) \cdot L\left(Y_{2} \mid Y_{1}\right) \cdot L\left(Y_{3} \mid Y_{2}\right) \ldots
$$

Here $L\left(Y_{i+1} \mid Y_{i}\right)$ is the conditional likelihood of $Y_{i+1}$ given $Y_{i}$ allowing for censoring, i.e.

1. If $Y_{i}>u, Y_{i+1}>u, L=f\left(Y_{i+1} \mid Y_{i}\right)$,
2. If $Y_{i}>u, Y_{i+1} \leq u, L=\operatorname{Pr}\left\{Y_{i+1} \leq u \mid Y_{i}\right\}$,
3. If $Y_{i} \leq u, Y_{i+1}>u, L=\frac{\operatorname{Pr}\left\{Y_{i} \leq u \mid Y_{i+1}\right\} f\left(Y_{i+1}\right)}{\operatorname{Pr}\left\{Y_{i} \leq u\right\}}$,
4. If $Y_{i} \leq u, Y_{i+1} \leq u, L=\frac{\operatorname{Pr}\left\{Y_{i} \leq u, Y_{i+1} \leq u\right\}}{\operatorname{Pr}\left\{Y_{i} \leq u\right\}}$.

This is similar to proposals for approximate likelihood for spatial processes by Vecchia (1988) and Stein, Chi and Welty (2004).

The estimating equations are unbiased, essentially because each component of the approximate log likelihood is.

Therefore, estimates are consistent and nearly unbiased.

Not asymptotically efficient, but we can estimate approximate variances through information sandwich approximation.

## Simulation Study

Use Matérn covariance function:

$$
C_{0}(t)=\frac{\theta_{1}}{2^{\theta_{3}-1} \Gamma\left(\theta_{3}\right)}\left(\frac{2 \sqrt{\theta_{3}} t}{\theta_{2}}\right)^{\theta_{3}} \mathcal{K}_{\theta_{3}}\left(\frac{2 \sqrt{\theta_{3}} t}{\theta_{2}}\right) .
$$

Here $\theta_{1}, \theta_{2}, \theta_{3}$ are respectively scale, range and shape parameters.
Simulate station locations in a $1 \times 1$ unit region - each sample consists of 100 days' independent data at 50 locations.

Employ two values of each of $\theta_{2}$ and $\theta_{3}$ (see Fig.).
Use two methods of ordering stations: mindist and maxvar.
PL1, PL2 are pairwise likelihoods using maxvar, mindist orderings respectively

Options for threshold: none, $u=1$ or $u=2$. Exact MLE available only in no-threshold case.

Four Matern covariances used for simulation study

Mindist Ordering

Maxvar Ordering

Two methods of ordering the spatial locations

The full simulation consists of 1000 replications used to compute:

1. Mean and RMSE of estimator
2. Coverage probability of nominal $90 \%$ and $95 \%$ confidence intervals without information sandwich correction (CP1, CP2)
3. Coverage probability of nominal $90 \%$ and $95 \%$ confidence intervals with information sandwich correction (CP3, CP4)

True scale $=1.0$, range $=0.3$, shape $=0.5$

## Conclusions from simulation study

1. Estimates generally unbiased except for shape parameter in threshold situation when true shape parameter is 2
2. RMSE is smallest for exact MLE, increases for approximate MLE as threshold rises
3. PL2 generally better than PL1 (i.e. prefer minimum-distance ordering of stations)
4. There is an overall problem of undercoverage of the confidence intervals. In many cases the information sandwich correction helps the situation, but not all.

## IV. APPLICATION TO THE RAINFALL DATA

Step 1: Estimating the GEV and spatial parameters

- Common distribution for all stations within a grid cell
- Fit GEV to exceedances over a high threshold based on pooled data from stations. In most cases I used the 0.975 empirical quantile but in a few cases a higher threshold.
- Use piecewise linear approximation for CDF below threshold.
- Transform to normality, fit Gaussian model. In many cases, the Matérn covariance did not result in a satisfactory model fit so I switched to the exponential model with nugget

$$
C_{0}(t)=\theta_{1} I(t=0)+\theta_{2} \exp \left(-\frac{t}{e^{\theta_{3}}}\right) I(t>0) .
$$

Estimation via pairwise likelihood based on ordering of stations that minimizes total distance (simulated annealing).

- Used natural threshold $u^{*}$, but also considered alternatives $u>u^{*}$ (a separate issue from the choice of threshold for initial GEV fit).

Example: Station 185, natural threshold $u^{*}=.5306$ (parameter estimates with SE by information sandwich in parentheses)

| Threshold | $\hat{\theta}_{1}$ | $\hat{\theta}_{2}$ | $\hat{\theta}_{3}$ |
| :---: | :---: | :---: | :---: |
| .5306 | 1.037 | .665 | 1.37 |
|  | $(.015)$ | $(.015)$ | $(.04)$ |
| 1 | 1.007 | .630 | .84 |
|  | $(.013)$ | $(.017)$ | $(.04)$ |
| 2 | 1.008 | .724 | .15 |
|  | $(.018)$ | $(.062)$ | $(.37)$ |

- Range $\theta_{3}$ decreases with increasing threshold, implying same Gaussian process does not apply to all levels.
- Generalization: replace $Z$ by a mixture of Gaussian processes?
- Despite the clearly significant difference in the models fitted to different thresholds, it does not seem to make much difference to the interpolations (specific example later)

Step 2: Interpolating the missing and censored observations in the Gaussian process

Use MCMC fixing spatial covariance parameters. 1000 warm-up iterations, followed by either 500 or 1000 iterations.

Step 3: Interpolating Gaussian process to a $30 \times 30$ array of locations within the grid cell

Use second phase of MCMC in Step 2, every 10th iteration generate full sample of values conditional on observed and imputed data at observation locations.

Suppose $\Sigma=\left(\begin{array}{ll}\Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22}\end{array}\right)$ where index 1 represents observation stations and index 2 represents the 900 interpolation points. Calculate Cholesky $\Sigma_{22}-\Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12}=U^{T} U$. Then simulate $Z_{2}=\Sigma_{21} \Sigma_{11}^{-1} Z_{1}+U^{T} Z_{0}$ where $Z_{0}$ is white noise.

A trick: All values of $U$ less than .01 were set to 0 . This speeds up computation time by a factor typically between 4 and 10 .

Step 4: Transform each predicted value back to original marginal distribution by inverting initial transformation step.

Step 5: Compute summary statistics

For each of the 900 interpolation points, average over iterations to obtain a single "predicted value" for that location for each day.

Also average over the interpolation points to produce a predicted value for grid-cell average, henceforth denoted PRED.

However we also utilize the information from the individual iterations to calculate a predictive distribution for the grid-cell average for each day.

Grid Cell Representation

Results for Grid Cell 185 (Threshold 0.5306)

Results for Grid Cell 185 (Threshold 1.645)

NCEP v. PRED (reconstructed) Values

Largest PRED day

CDF of $P(P R E D<=N C E P)$

Largest NCEP day

Results for Grid Cell 104

NCEP V. PRED (reconstructed) Values

Largest PRED day

CDF of $P(P R E D<=N C E P)$

Largest NCEP day

Results for Grid Cell 222

NCEP v. PRED (reconstructed) Values

CDF of P(PRED<=NCEP)

Results for Grid Cell 41

50-Year Return Values for Cell 104 ( $\mathrm{B}=$ Boulder; $\mathrm{F}=$ Fort Collins)

## Computing grid cell return values

For OBSV: use same threshold as used in constructing the spatial analysis (in most cases, this was set at 97.5 th percentile)

For PRED and NCEP: calculate RV50 (with delta method SE) using 95th, 96th, 97th, 98th, 99th percentiles as thresholds. Use the estimate for the lowest threshold that's consistent with every estimate above it, as judged by the SE.

OBSV 50-Year Return Values

PRED 50-Year Return Values

NCEP 50-Year Return Values

Ratio OBSV:NCEP

Ratio OBSV:PRED

Ratio PRED:NCEP

## VI. SUMMARY AND CONCLUSIONS

- Return values computed from PRED are much closer to those computed from NCEP than the original estimates computed directly from the observational data
- However, clear discrepancies remain. In most cases, the return value computed from NCEP still underestimates that from PRED.

## Future Work: Statistics

- Incorporate covariates and/or spatial dependence into parameters of marginal distributions
- Consider alternative spatial dependence models or extend to spatial-temporal processes
- Alternatives to Gaussian processes, such as mixtures?

## Future Work: Climatology

The results show clearly that there is a smoothing effect return values based on grid-cell averages are smaller than those based on individual observation stations.

However, NCEP seems to be taking this smoothing effect too far.

Could a more realistic spatial statistics representation of sub-grid-cell processes lead to improved parametrizations in climate and weather-forecasting models?
